Human Intestinal Parasitic Infections and Environmental Health Factors in Rural Egyptian Communities

RESEARCH REPORTING SERIES

Research reports of the Office of Research and Development, U.S. Environmental Protection Agency, have been grouped into nine series. These nine broad categories were established to facilitate further development and application of environmental technology. Elimination of traditional grouping was consciously planned to foster technology transfer and a maximum interface in related fields. The nine series are:

1. Environmental Health Effects Research
2. Environmental Protection Technology
3. Ecological Research
4. Environmental Monitoring
5. Socioeconomic Environmental Studies
6. Scientific and Technical Assessment Reports (STAR)
7. Interagency Energy-Environment Research and Development
8. "Special" Reports
9. Miscellaneous Reports

This report has been assigned to the ENVIRONMENTAL HEALTH EFFECTS RESEARCH series. This series describes projects and studies relating to the tolerances of man for unhealthful substances or conditions. This work is generally assessed from a medical viewpoint, including physiological or psychological studies. In addition to toxicology and other medical specialties, study areas include biomedical instrumentation and health research techniques utilizing animals — but always with intended application to human health measures.

This document is available to the public through the National Technical Information Service, Springfield, Virginia 22161.

16. ABSTRACT

A survey of common intestinal parasites was completed in three areas of the Egyptian Nile Valley: The Nile Delta, Upper Middle Egypt and Upper Egypt. The relocated Nubian population was also included. The total sampling included 15,664 persons in 41 villages. More than 95% attended and approximately 90% provided a stool specimen. Environmental health observations and measures were made in each of the households from which a family was selected and in the village environs. Sampling within a study site (which included one or more villages) was designed to provide a probability of selection. Stool specimens were preserved and examined for parasites and ova at a central laboratory using the MIFC technique.

The findings indicated a very low prevalence for all helminthic infections. A low prevalence of Ancylostoma and the Ascaris infections was found.

Important features such as the household stable, the zir (a water storage container), and cooking fuel were evaluated. Considerable information on water and wastewater use was developed. Also, a review of the available information on the parasitic infections of interest and environmental health conditions for rural Egypt was compiled for the first time.

DISCLAIMER

This report has been reviewed by the Environmental Research Laboratory, U.S. Environmental Protection Agency, Athens, Georgia, and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the U.S. Environmental Protection Agency, nor does mention of trade names or commercial products constitute endorsement or recomendation for use.

FOREWORD

After centuries of annual flooding and drought, the construction of the Aswan High Dam has provided effective flow control to the River Nile as it enters the fertile Egyptian Nile Valley. The dam has resulted in the production of hydroelectric power for municipal, agricultural, and industrial use, and the continuous availability of water has increased agricultural productivity. Optimum benefits from a project of this magnitude cannot be fully realized, however, until the major environmental, agricultural, social, economic, and public health impacts have been incorporated into strategies for managing the water resources within the basin. In 1975, the U.S. Environmental Protection Agency and the Ford Foundation began support of a 5-year, multifaceted research program conducted by the Egyptian Academy of Scientific Research and Technology and related institutions and the University of Michigan to provide the information needed for comprehensive water quality management in the Nile Valley.

Although the project addresses issues of vital importance to Egypt, the knowledge gained also will be of significant benefit to the general scientific community. For example, water resources management models developed for the Nile Basin can be applied to some river basins in the United States.

This report, a companion document to Schistosomiasis in Rural Egypt (EPA-600/1-78-070), describes a survey of common intestinal parasites in the Nile Delta, Upper Middle Egypt, and Upper Egypt that was part of the public health portion of the U.S.-Egyptian project.

PREFACE

The Aswan High Dam was built for the purpose of water storage, river flow control and hydroelectric power production. The fulfillment of these goals is of vital importance to Egypt's agricultural and industrial development programs. This can be easily realized since the River Nile constitutes 90% of Egypt's fresh water resources and the present population of 38 million people inhabits approximately 4% of the land with the rest barren desert. Nevertheless, since its inception, the Aswan High Dam has been under unprecedented attacks in the news media and scientific literature. It has been blamed for causing serious ecological perturbation that resulted in reducing the fish population in the Mediterrean Sea, lowering the fertility of the Nile Valley, and markedly increasing schistosomiasis in Egypt. Our study, Schistosomiasis in Rural Egypt, however, indicated a marked decline in the disease prevalence over the past 40 years.

These research findings are the outcome of a comprehensive ongoing project dedicated to the study of the River Nile and the impacts of the Aswan High Dam on multipurpose river uses. This includes irrigation, community water supply, fishing, recreation, transportation, etc. The aim of this project is to provide the decision makers in Egypt with river management alternatives compatible with government goals for economic development. This includes the assessment of trade-offs and predictions of the outcome of each river resource management alternative. This is a joint project between the Egyptian Academy of Scientific Research and Technology and the University of Michigan. The technical and financial support of the U.S. Environmental Protection Agency, the Ford Foundation, and the World Bank is highly appreciated.

ABSTRACT

A survey of common intestinal parasites was completed in three areas of the Egyptian Nile Valley: The Nile Delta, Upper Middle Egypt and Upper Egypt. The relocated Nubian population was also included. The total sampling included 15,664 persons in 41 villages. More than 95% attended and approximately 90% provided a stool specimen. Environmental health observations and measures were made in each of the households from which a family was selected and in the village environs. Sampling within a study site (which included one or more villages) was designed in a fashion to provide a probability of selection. Stool specimens were preserved and examined for parasites and ova at a central laboratory using the MIFC technique.

The findings indicated a very low prevalence for all helminthic infections. A low prevalence of Ancylostoma and the Ascaris infections was found.

Important features such as the household stable, the zir (a water storage container), and cooking fuel were evaluated. Considerable information on water and wastewater use was developed. Also, a review of the available information on the parasitic infections of interest and environmental health conditions for rural Egypt was compiled for the first time. This information is necessary for the design of accurate parasitic surveillance programs.

This study is the result of a joint effort by the University of Michigan and the Egyptian Academy of Scientific Research and Technology that was funded by the U.S. Environmental Protection Agency, The Ford Foundation, and the World Bank.

TABLES, CONTINUED

ACKNOWLEDGMENTS

This work required the examination of almost 15,500 stool specimens which had been preserved in small 10 cc plastic bottles and shipped to the parasitology laboratory at the High Institute of Public Health from the various study sites. The laboratory was directed by Associate Professor Rashida Barakat, M.D. and supervised by Lecturer Ebtesam Omar, M.D. In addition, there were seven employees, all doctors of medicine who, as an extension of their training in parasitology, helped in the examination of these specimens. To them we are deeply indebted.

CHAPTER I

INTRODUCTION

BACKGROUND

This report is the second and final part of an analysis of data collected in rural Egypt on parasitic infections and key environmental variables. The study objectives, study design and methodology have been described in detail in the first part entitled Schistosomiasis in Rural Egypt: A Report of U.S.-Egyptian River Nile and Lake Nasser Research Project (Miller et al., 1978). Salient features of the study design and methodology are included in this report for purposes of clarity.

The objectives of this study were to obtain information on the prevalence of helminth and protozoan infections in selected rural Egyptian communities in collaboration with the River Nile-Lake Nasser Study, a joint University of Michigan-Egyptian Academy of Scientific Research and Technology project. The River Nile-Lake Nasser Project's prime objectives have been to evaluate the overall environmental impact of the Aswan High Dam (AHD).

Diverse disciplines have been incorporated into this project in an attempt to obtain an integrated picture of changes occuring in the Egyptian Nile basin, following the formation of the large man-made lake, Lake Nasser. It was in this vein that the design of the study reported here was formulated.

The parasites screened for are typical helminth and protozoan infections of the intestinal tract, common to tropical and semi-tropical areas of the world and detected by the identification of the characteristic ova, cysts or tropozoites in stool specimens. Frequently these infections are associated with water supply and use, as well as waste water disposal practices. It was felt that basic fundamental knowledge of the current prevalence, distribution and secular trends were important to determine the magnitude of the water management schemes now under development as a result of the formation of Lake Nasser. Furthermore, the implication of changes in prevalence or transmission of these parasites, directly or indirectly, as a related function of the lake formation was explored in an attempt to more completely follow the impact of the High Dam construction in the health of the rural Egyptian population.

Table 1 is a list of these parasites and a brief description of their principal mode of transmission. Some of these parasites have no direct relation with water supply, but were included as the methods of examination used to reveal these infections.

Endolimax nana	intestinal amoeba	man-man

* The ova of this genus are not morphologically differentiable.

Specifically, the objectives of this study were to:

1. Obtain and critically review all available past information of the prevalence, distribution, incidence and transmission of the selected parasites in an effort to establish baseline and trend data for the rural Egyptian population.

2. Obtain measures and estimates of the point prevalence of the selected parasites in rural Egyptian communities.

3. Show the changes in the epidemiology of the selected parasites through comparisons with assessed historical data.

4. In general, collect, assess and analyze environmental health data in parallel with the parasite surveys in the rural study sites.

5. Illustrate any village environmental effects on the transmission of the selected parasites studied.

6. Suggest appropriate needs in light of the findings.

THE SETTING: EGYPT

This study included 41 rural villages in 4 major and separate study areas in rural Egypt. In order that the reader have a clear picture of the study areas, and an understanding of the rationale in selecting these sites, the following notes have been prepared.

Egypt is made up of several distinct sectors. The largest sector is made up of the eastern and western deserts which account for over 90% of the land mass. The area is populated rather sparsely by nomads, with few small settlements. Located in the western desert are several more populated oases. El Kharga and El Dakhla oases, in what is referred to as the new valley, are sites of recent agricultural development and currently have a combined population of about 76,000 persons. There are also populated settlements along the western Mediterranean shoreline and along the Suez Canal. The remaining 99% of the Egyptian population is compressed in the Nile Valley and in the Nile Delta, 3.5% of the country's land mass. The population density in these areas has been estimated at 2,400 persons per square mile (Waterbury, 1971). For the purposes of this study, the Nile Valley has been divided into:

(a) the delta or lower Egypt,
(b) Upper-Middle Egypt, between the delta and Assyut, and
(c) southern or Upper Egypt located between Assyut and the Aswan High Dam (AHD). Before the AHD was constructed, there existed a people called Nubians located between Aswan and the Sudanese border. When the new lake inundated this area, the Nubians were resettled, en masse, in Kom Ombo, an agricultural plain about 75 km north of Aswan, and in Kheshm El Girba, in the Sudan.

The population of Egypt has always been predominatly "rural;" described by Scott (1937) as persons "whose habits of life bring them into contact with fields and canals where infestations with parasites may be acquired." In 1937, 11.49 million persons were living in a rural setting; 72% of the total population of 15.92 million. By 1960, 62% were rural. The rural population has further declined to 56.1%, according to the last census survey conducted in 1976 (Capmas, 1976).

The distribution of the Egyptian population is as follows: 60% of the population resides in Cairo or north of Cairo in the Nile Delta or Lower Egypt, 23% live in Upper-Middle Egypt, and 12% live in Upper Egypt (Omran, 1973). Males compromise 53% of the total population (Capmas, 1976).

CHAPTER II

CONCLUSIONS AND RECOMMENDATIONS

The key results of this investigation were; 1) that the parasite infections Ascaris and Ancylostoma are not elevated to high levels of prevalence at any of the village studies sites, 2) the high prevalence of Entameoba infections were present at all study sites, 3) the Nubians have not been adversely affected by their relocation in respect to the parasites studied or environmental health conditions which were greatly improved and 4) the most extensive descriptive data on environmental health conditions for rural Egyptian villages has been collected and assessed.

Conversations with officials from the Ministry of Health (the Secretary General of parasitic diseases) in 1978 before the field activities indicated that hookworm infections were low throughout Egypt, but that Ascaris was quite common in both the urban and rural sectors. The surprising findings of very low number of persons infected with Ascaris in the sample remains, in part, unresolved.

It had been indicated that piperazine had been widely distributed by the rural health units and centers in the period just previous to the field collection of specimens. This, in part, may have caused a sharp reduction in prevalence. Also, in Upper Egypt and in Nubia the prevaling opinion of the local practitioner was that both Ascaris and Ancylostoma were infrequent infections. Zawahry's findings in 1964 in Old Nubia are in agreement with these attitudes, and the results from New Nubia and Aswan are also consistent. It is with considerable reserve, however, that a figure of 8.4% is presented as a reasonable estimate of Ascaris infection in the Nile Delta. A more specialized small scale study aimed at establishing current rural health programs in the control of Ascaris transmission and concurrent prevalence surveillance is recommended. The primary design of such a study should be directed at obtaining the minimum amount of evidence necessary to determine the order of magnitude of Ascaris infestation in the population.

Based on the assumption that intestinal protozoan infections which have a fecal-oral route are an indicator of hygienic conditions, the high prevalence of the Entameoba infections indicates a strong need in this area. It is encouraging that E. histolytic was not found as frequently as did Weir et. al. (1952). Rather, E. coli infections were the most frequently identified Entameoba, at about 10 to 1 ratio. E. coli is not considered a pathogen and specific measures for control are not recommended. It is expected that an increase in water availability and water use would improve the hygienic conditions of the rural Egyptian villager and would result in an improvement in his/her well being. Indeed, it is water, specifically the supply of clean,

cheap, ready available water that is wholeheartily recommended. Furthermore, any system that would increase the quantity, quality and use of water by the villagers should be considered. Appropriate technology rather than imported technology should be stimulated to meet these needs. In respect to water use and appropriate technological developments the household water container, the zir, must be taken into consideration. As revealed in the descriptive environmental health data, the zir, the stable and the fuel materials used for cooking are high priorities for improvement of the immediate environment of the Egyptian villager. Historical information indicated that the progress for installing latrines have been fairly well accepted and that standpipes or latrines are not a novelty in rural Egypt. This is encouraging, although there still remains a strong need for waste disposal in the sample from Upper-Middle Egypt.

The Nubians, in terms of parasitosis, were not found to vary greatly from their fellow Saidis (Upper Egyptians). This is a positive finding in that following the relocation of the Nubian tribes, it was expected that there would be a fall in their health status as measured by these studies. The same recommendations applied, therefore, to the Nubians in that improved water and hygiene measures are needed.

CHAPTER III

REVIEW OF LITERATURE

PARASITES STUDIED

There is no previous review of surveys available on the prevalence, distribution and transmission of these parasites in the Egyptian population. It is understandable that if historical information can be found, it must be assessed before a parasitic survey can be planned effectively. The search for historical data paralleled the assessment of the literature for schistosomiasis that has been published in the first part (Miller, et al., 1978). Like the information found for schistosomiasis, more historical data was uncovered than had been expected, although there are obvious restrictions on the interpretation of this past data. Important and fundamental aspects of the prevalence and distribution of these parasites were locatable. The principle reasons for restricting the direct comparison of these different studies are: the differences used in detecting the various parasitic infections in the excreta, and in the methods used to sample the human population from which specimens were obtained. Standardization in detection of parasites and ova in the stool remains to be established and is a recurrent source of criticism. However, sampling methodologies have clearly established that sample selection, based on probability is necessary before statistical measures, whether descriptive or analytical, can be applied. The latter aspect was frequently ignored altogether, where as detection methods were invariably elaborated on. In Table 2, a summary of the studies, found in the search for historical data, is given by area, date, author and parasite. Filariasis and leishmaniasis were not screened for in this project, but were included in Table 2, not only for completeness but also because of their potential severe impact on the health status of rural populations in less developed areas. Both studies by Shawarby, et al. (1965) and Cahill, et al. (1966) had wide coverage and impressive sample sizes. The reader is referred to these studies and the others cited in Table 2 for details on prevalence and distribution that are not shown in the table.

In parallel with the historical findings on human schistosome data, more surveys were completed in the Nile Delta than in the other sectors of the country. Also, the Nile Delta had consistently higher prevalences, regardless of the parasite or year, when compared to any other area of the country. This was also true for the schistosomes. It is unfortunate that the greater proportion of the rural Egyptian population (59.4%) is located in this same area.

Filariasis and leishmaniasis show very distinctive focal distributions in the Nile Delta. Both studies are now over a decade old, having been

*Indicates that the respective parasite was not searched for in the study.

completed in the 1960's. Hopefully, surveillance will be continued on these two important parasitic infections in order to determine if there have been more recent changes in prevalence or distribution.

Overall, it would appear that hookworm (Ancylostoma) infections are not as prevalent as the roundworm (Ascaris) infections. Chandler's studies on hookworm in 1954 found considerable variation (8.3% and 36.0%) in different village sites in the governorate of Qalyubya. This variation was determined by a single investigator and his respective research team, thus variation due to methodological differences were most likely minimal, thus indicating a strong focal distribution for hookworm infections. The differences in prevalence found between the other investigations support this hypothesis. However, the only historical data on a country-wide basis for hookworm and roundworm were made by Scott in the 1930's (Scott, 1937a and Scott 1937b). The expectation has, and still is, that hookworm would be consistently high, 90% to 100%, in the rural population of Egypt, and Scott (1937c) attempts to explain why it was not. It is interesting that no cases of hookworm were seen by Rifaat (1958) or Zawahry (1964) in old Nubia. Furthermore, Scott (1937a) found roundworm infection lowest in the Aswan area.

ENVIRONMENTAL HEALTH CONDITIONS IN RURAL EGYPT

The following material on environmental health conditions in rural Egyptian populations also appears in a previous report (Miller, et al., 1978). Since analytical aspects are included in this report and employ this information, this portion of the text is reproduced here for reasons of convenience for the reader.

The historical information sought for environmental health conditions in Egypt included the following:

1) General village sanitation
2) Water supply wastewater practices
3) Wastewater practices
4) Housing conditions
5) Refuse or solid waste practices.

Detailed analytical information on these parameters is rather limited for Egypt as a whole. Several local studies are available, however, for the delta and for Old Nubia. Data from these studies have been provided in somewhat greater detail.

Amin and Zaghloul (1959) reviewed the administrative organization of the EMH environmental services, but provided little data. They did point out that by 1959, protected rural water supply had been provided to each village over 1,200 persons. Generally, water was pumped from an underground source to elevated tanks which supplied a limited number of public water standpipes (one or more taps fixed to a vertical concrete slab). This water supply project had been started in the 1940's and by 1960 fairly wide coverage was obtained. In 1975 all villages had at least one source of water. The goal of

one standpipe per 300 persons was 90% to 95% completed by this time (Furnia, 1975). This is very impressive when compared with the water supplies available in the rural villages of other similar developing countries. Installation of latrines in the rural areas has been less successful (Furnia, 1975).

The major refuse problem in Egyptian villages is animal waste (Headlee, 1933; Weir, et al., 1952). Animal manure is still commonly used for composting and for cooking fuel. The compost heaps and the drying dung cakes cause a serious sanitation problem by providing ample sites for fly breeding. For the most part, solid waste in the conventional western sense does not exist in Egyptian rural villages. Only infrequent isolated litter piles may noted in typical villages. However, where multistoried housing projects have been constructed and in urban areas there are extensive solid waste problems. On the village level very little solid non-organic material is discarded. This picture is now beginning to slowly change as the population grows and as more consumer goods become available to the rural populations.

Focusing on the delta, Headlee (1933) made detailed environmental observations on the rural village of Rushdy, Qalyubia. No clinical data were provided but excellent maps were made showing the defecation sites in the village. Samples were taken from these sites and examined for helminthic parasites. Enterobius, Ascaris, Trichuris, Hymenolepis and Ancylostoma were detected in the samples.

According to Scott (1937), this indiscriminate habit has important implications concerning hookworm transmission. If the same defecation sites were frequented, then hookworm transmission would be favored. However, defecation sites were scattered and, as Scott (1937) showed, the prevalence of hookworm was not as high as might be expected.

Headlee (1933) also observed the still common practice of disposing household wastewater in the village streets and that the presence of a stable attached to the home contributed to the intense fly problem Farooq, et al. (1966a) commented that village conditions in the delta had changed little since Headlee's report.

Weir, et al.'s (1952) study (1952) of the same general area (Sindbis, Qalyubia) confirmed Headlee's observations. Weir, et al. (1952) also found that 31% of all the homes in the study area had latrines, out of a total of 4,878 houses examined, and 10% had wells. Flies in the study site were noted in large numbers. Counts were made monthly on the fly populations. These counts showed seasonal fluctuations with low numbers in the middle winter months and high counts for the remainder of the year. Measures were taken to reduce the fly populations, and it is interesting to note that during a two year period in the areas where control was maintained, infant mortality was markedly reduced. This is a very important observation. No other environmental measure tested during this study demonstrated any improvement in infant mortality, indicating the overwhelming importance of flies as vectors of serious infantile diseases.

In 1966, Farooq, et al. (1966a), found that 87.6% of the people in Beheria, in the northwestern delta, had piped water, a 77% increase in the number with piped water since 1952. The exact distribution of people with or without piped water is shown in Table 3. Ten and one half percent of the sample used canal water exclusively.

TABLE 3

DISTRIBUTION OF EXAMINED POPULATION BY SOURCE OF WATER SUPPLY

AFTER FAROOQ, et al. (1966)

Water Supply	Number of People	Percentage Distribution
Canal	1248	10.5
Piped Water	10466	87.6
Other	70	0.6
Not Stated	160	1.3
TOTAL	11944	100.0

Table 4, reproduced from Farooq's study, shows the number and distribution of people by type of house. There were considerable differences between divisions with an overall 58.5% living in stone or redbrick houses and 40.3% living in mud or mud brick houses. Farooq, et al. (1966) also determined the number of persons with a cowshed and the number and distribution of latrines. They found that just over half of the population do not have cowsheds, 32.9% have adjoining cowsheds and 14.4% have separated cowsheds. The latter group was considered to be in a higher economic class than the former two. At these study sites, 52% of the population was found to have latrines; 10% had latrines and did not use them (It would be interesting to know just how this was determined.); and 36.4% did not have a latrine. This indicates that there is an increase in the number of latrines in the homes since Weir, et al.'s (1952) time.

As shown in the prevous sections on schistosomiasis, all the above environmental parameters influenced the transmission of infection, with the exception of latrines which showed a marginal decrease in prevalence, and only when age and type of house were controlled for.

In Upper-Middle Egypt only the report by Hassouma (1975) is available on a rural housing survey. Table 5 is reproduced from this report to the Egyptian Ministry of Planning. A majority of the houses obtained water from

public standpipes (54%). However, a significant number (14%) had water piped to the home. For 12% of the homes, water came from the canals.

Hassouma (1975) also found that 6.4% of the houses were converted to sewage systems and that 10% had septic tanks. These fascinating observations, especially the presence of the sewage systems, beg the question "What did the author use as a definition or 'rural'?" Unfortunately, no answer was provided. However, over half of the houses surveyed did not have a latrine.

TABLE 4

DISTRIBUTION OF EXAMINED POPULATION BY TYPE OF HOUSING

AFTER FAROOQ, et al. (1966a)

Type of House	Number of People	Percentage Distribution
Stone or Red Brick	6988	58.5
Mud Brick or Mud	4811	40.3
Other	7	0.0
Not Stated	138	1.5
TOTAL	11944	100.0

Upper Egypt

In the area between Assyut and Aswan, only sketchy information exists and most of what does is centered on the Aswan environment only. In 1965, Aswan City had no sewage system and the large fertilizer plant (The Kima Company) nearby was inadequately treating its waste-water which was being discharged into the Nile (Messina, 1970). Other (Eachmann, 1965; Satti, 1970) reporting to the WHO found the Aswan urban area poorly developed in respect to waste-water management.

Old Nubia

In 1960, Abdady and Shalash (1966) from the National Research Center, Cairo, completed a one-year survey on the Nubians which examined the environment and livestock resources. Selection of families was based on the family register at each village and selections were representative and proportional to the 1960 census. It was a well-designed study. Each tribe was represented and Table 6 shows the number of families selected, by tribe, village and the location of the village on the eastern or western bank of the Nile. Table 7 shows the housing conditions for each area. Table 8 shows the type of water supply, lighting and food storage in the house. Whereas this table points out that no sewage system existed, the general description of the text stated that toilets were located inside the houses in the Fadiga area, and outside

for the other two tribes. No numbers were provided on how many were available. Also included in this discussion was that the hand pumpwells located in the Fadiga area usually did not function.

TABLE 5

WATER AND WASTE-WATER FACILITIES IN UPPER-MIDDLE EGYPT

AFTER HASSOUMA (1975)

TYPE OF FACILITY	VILLAGE					
	Faraskour		Queaa		Deshna	
	No.	%	No.	%	No.	%
Water Supply						
Piped Inside	36	13.6	4	1.6	48	35.8
Piped Outside	106	40.2	194	74.6	54	40.3
Hand Pump Inside	120	45.4	8	3.0	8	6.0
Canal	2	0.8	54	20.8	24	17.9
Waste-Water Disposal						
Sewer	34	6.5	4	0.8	44	16.7
Septic Tank	94	1.8	8	1.6	38	14.5
Latrine	134	25.5	219	36.9	46	17.6
None	264	50.2	260	53.1	134	51.1

A description of the village areas was included in the report. In the Fadiga tribal areas, houses were in rows with 20-30 meters from one row to the next, spreading out over a 500 by 600 meter area. Houses made of combinations of mud, rock and cane were architecturally similar to the American Indian hogan with walls extending out to encompass a courtyard, a guest room and a stable. A characteristic feature of Nubian houses is the decoration of the walls, both on the inside and outside. There is a prevailing attitude throughout Egypt that the Nubians are exceptionally tidy and honest.

Floor plans of the old Nubian houses have been prepared by Fernea (1973).

In brief, Egypt has had a progressive plan for the provision of a protected water supply to the rural areas since the 1940's. A visit to the rural areas readily confirms the widespread distribution of rural water supply. This

project's findings indicate fewer persons visiting canlas or unprotected water courses for their water, but still evident in the rural areas are the women washing clothes and dishes in the canals, the children bathing in the canals and the farmer irrigating his fields by ancient methods requiring contact with canal water. Generally, the sanitation conditions in the villages of Egypt have improved somewhat since Headlee's study (1933). In terms of crowding, they may have become worse.

TABLE 6

TRIBE, LOCATION, VILLAGE AND NUMBER OF FAMILIES

SELECTED IN NUBIA, 1960

AFTER ABDADY AND SHALASH (1966)

Tribe	Location on Nile Bank	Village	Number of Families Selected
Fadiga	West	Ballana	275
Fadiga	East	Abu Simbel	170
Arab	West	As-Sabu'a	75
Arab	East	As-Sangari	75
Kanoose	West	Sarf-Hussein	75
Kanoose	East	Kask Tamna	75

In the following villages, irrigation pumps and canals had been installed:

a) Dikka
b) Al-Alaqi
c) Aniba
d) Tushka
e) Aramna
f) Abu Simbel
g) Ballana

TABLE 7

HOUSING CHARACTERISTICS, OLD NUBIA, 1960

AFTER ABDADY AND SHALASH (1966)

Arab	0	93	57	0	150
Kanoose	0	10	140	0	150

CHAPTER IV

MATERIALS AND METHODS

This study is separated into two major subdivisions. The first, termed the "Downstream Study", is a comparison of environmental and epidemiological health parameters at different village sites comprised of indigenous rural populations located downstream from the AHD, excluding the relocated Nubians. The second, termed the "Nubian Study", is concerned with the Nubian populations displaced by the formation of Lake Nasser. The results of both investigations have been analyzed for correlations with environmental and epidemiological alterations resulting from the construction of the AHD.

DESCRIPTION OF THE "DOWNSTREAM STUDY"

The Downstream Study is designed to assess the impact of the formation of Lake Nasser on indigenous rural populations in Egypt downstream from the AHD. The design rationale is based on a comparative approach for which data are collected from more than one site. Thus it can be determined whether changes occurring over time or in a given location are unique, and casual relationships can be developed accordingly.

Three areas have been selected which afford maximum comparability. The first, from an area likely to be affected by Lake Nasser, are the rural villages north of the city of Aswan and south of Kom Ombo. The two other areas are Beni Suef, between the delta and Assyut, and Kafr El Sheikh, in the north cantral Nile Delta. For the sake of convenience, the three "areas" in which rural villages were selected for the downstream study are referred to as the Aswan, Beni Suef, or Kafr El Sheikh study area.

In each of these three governorates, rural villages have been selected based on: a) how representative the village is of the area; b) accessibility; c) population composition and size; and d) the presence or absence of a rural health center or unit. The selection of villages from these three areas was also based on information obtained from past studies. It was clear from these studies that Upper-Middle and Upper Egypt had frequently been excluded, with a far greater number of past surveys being carried out in the delta. Within the delta, more prevalence information on schistosomiasis was available for Qalyubia than all the other delta governorates combined. Sites in Kafr El Sheikh were selected, therefore, to help correct this deficiency of information. Also, historical data indicated that the northern delta, in which Kafr El Sheikh is located, had maintained the highest schistosome prevalence in rural Egypt. The data from Kafr El Sheikh provided the ultimate baseline prevalence for this study, as opposed to areas farther south and geographically more central. Villages were selected in the Beni Suef area as representative of Upper-Middle Egypt for the simple reason that recent data

indicated that the distribution of S. mansoni infections were slowly migrating south from the Nile Delta into this area (Hussein, 1972; Alamy and Cline, 1977). Sporadic cases of S. mansoni had been seen in Beni Suef by Hussein (1972). It was therefore important to determine if S. mansoni cases could still be found or were increasing.*

DESCRIPTION OF THE "NUBIAN STUDY"

This study is designed to measure the changes in the prevalence of parasites in the Nubian population following displacement due to the formation of Lake Nasser. The Egyptian Nubians, a population of 45,000 to 50,000 persons, resided in villages scattered along the banks of the Nile, south of Aswan to the Egyptian border. This population was displaced by the rising waters of the new lake in 1964. The Nubians, who were rural in nature and composed of three different tribes, were moved en masse to Kom Ombo, 40 kms downstream from the AHD. For all practical purposes, the entire population was resettled in this area. The new villages bear the same names as those from which the settlers originally came and, in addition, retain their respective locations as in old Nubia with the Kanoose tribe in the north, the Arab in the middle and the Fadiga in the south. No other formal arrangement was made by the government to have resettlements in other areas. However, there remains an original Nubian community located on the eastern Nile bank just north of the old Aswan dam, called Kazan Sharq. This is the southernmost village in Egypt with the exception of a very small village located on an island in the reservoir that inundates the area between the old and new dams. No resettlement sites are present on the lake shore. The high ground surrounding the lake is harsh, barren and, according to Dazo and Bile's (1971) survey, uninhabited with the exception of the Abu Simbel community 300 km upstream from the AHD. Although Abu Simbel does not constitute a rural/agricultural community, it is the only permanent lake shore site currently inhabited. In 1971, the population of Abu Simbel was 134 and was comprised mostly of government workers employed in the maintenance of the Abu Simbel temples. Abu Simbel does not represent displaced Nubian communities. Observations made during a 5 day trip on Lake Nasser in May, 1977 confirmed these findings. Earlier in the Review of Literature, Dazo and Biles (1972) found that 9% of the population there had S. haematobium infections. No other helminthic infections were observed.

The Nubian study includes three major sites between which comparative studies have been made: a) the old, no longer existing Nubian villages of Kurta, El Malki, and Ballana; b) the correspondingly resettled sites at Kom Ombo; and c) the original Nubian community, Kazan Sharq, located on the eastern Nile bank just north of the old Aswan Dam.

---

* (The determination of a change in the distribution of S. mansoni infections to the south was an overriding consideration in respect to the selection of appropriate sites for the surveillance of the other helminthic and protozoan infections. In addition, there was no historical information that suggested that by selecting village sites in the Beni Suef area aspects of the distribution of these other parasites would be missed or overlooked.)

Abu Simbel had to be excluded because it does not represent the Nubian population. Also excluded are the lake shore sites which are yet to be developed, and the Lake Nasser fishermen. As mentioned previously, a joint WHO-EMH inter-region project (IR-065 RDF/71/217) is currently being organized to investigate the health status of the Lake Nasser fisherman population.

Definitions for pre- and post-AHD are needed to establish the point in time for describing "before" and "after" conditions necessary for making comparisons between studies. Pre-dam is defined as the period before the discharge of the Nile was controlled by the AHD. Post-dam is defined as the period from 1964 to the date of this study (1976). The construction of the AHD was not completed until 1974, but as mentioned earlier, the coffer dam, constructed to divert the flow of the river around the area where the AHD's foundations were being laid, was removed in 1964 and the ensuing floods have since been trapped behind the AHD. The reservoir reached maximum volume in 1976. The term "significant" is defined as a meaningful increase in the prevalence of a selected parasite when comparing the results from different study sites used in this research with results from other villages employed by other workers. Frequently, the number of cases may be large enough to demonstrate statistical significance between results differing only in one or two percentage points. Whereas this would constitute statistical significance, it would not be meaningful.

DATA ACQUISITION

The two major categories of data collected were: historical baseline data and data collected from field studies that included environmental health data and epidemiological morbidity data for the selected parasites mentioned. The implementation of the field survey was guided by a program evaluation review technique (PERT) diagram.

The PERT diagram identified and numbered each individual activity or job to be carried out. The time in days required to complete each job was estimated and then each job was placed appropriately in the sequence. Except for the first, each preceding job or jobs had to be completed before the following one could be started. Thus, projected dates of completion were calculated. Moreover, free slack, or the amount of time that a previous job could be postponed without delaying the overall projected completion time, was estimated. The estimated time to complete the field activities up to the point of analysis of the data was 265 days. The actual time for completion was approximately 260 days.

SPECIFIC DATA COLLECTED

The categories for data which were collected are:

1) environmental health parameters:

   a) water supply and use
   b) sewage disposal
   c) housing
   d) irrigation practices

2) epidemiological parameters:

   a) age-sex structure of the sample population
   b) parasite prevalence.

It may be noted that agricultural irrigation methods have been included as an environmental health parameter. Generally, irrigation schemes, as such, do not fall within the realm of environmental health specialties. However, in Egypt, as in a number of other tropical developing nations, agriculture practices and especially irrigation methods play a central role in the transmission of many parasitic diseases. Moreover, it is the open canals and drains which are associated with present day irrigation in Egypt that provide excellent habitats for snail vectors. For the rural populations of Egypt, canals long ago became a way of life. The convenience the canals have provided in the rural villages for domestic water for washing, bathing, swimming, drinking, and ablutions is readily evident to the visitor.

Data acquisition forms (questionnaires) were designed and translated into Arabic. These forms serve as a list for the various parameters under study. The original English data forms are included in Appendix 2, in part one (Miller, et al., 1978).

Considerable peripheral data are included in the survey listed on the data forms. As much data as possible were obtained concerning all the environmental parameters in the hope that nothing would be overlooked simply because it was not requested. Secondly, data were needed to control for certain variables; for example, age, sex, occupation, etc. Indeed, the study was originally designed under a much broader scope specified by the needs of the River Nile - Lake Nasser study of which this work was a part.

SELECTION OF FIELD SURVEY SITES

A total of ten health units and centers were selected in Kafr El Sheikh and in Beni Suef based on criteria mentioned in the description of the downstream study. The name of the health unit or center does not always correspond to the name of the village from which the sample population was selected. Sometimes more than one village was sampled by the health unit or center. This is true also for Aswan and for the Nubian sites.

In Kafr El Sheikh, the selected health units of centers, also termed "study sites", and their code numbers shown in parenthesis, were:

a) health unit El Agazein (16): only the village El Agazein was sampled;
b) health center a (17): only the village El Hamra was sampled;
c) health unit Mahalet El Kasab (18): only the village Mahalet El Kasab was sampled;
d) health unit Mahalet Mousa (19): Mahalet Mousa and El Nataf were sampled;
e) health unit Sheno (20): two villages, Sheno and Reskit El Shenawi were sampled.

In Beni Suef, the selected health units or centers and their code numbers were:

a) health center Barout (11): only the village Barout was sampled;
b) health unit Sherif Pasha (12): only the village Sherif Pasha was sampled;
c) health unit Naiim (13): two villages, El Ammana and Abu Mousa, were sampled;
d) health center Beni Adi (14): only the village of Beni Adi was sampled;
e) health center Ashamant (15): only the village of Ashamant was sampled.

Both Kafr El Sheikh and Beni Suef are the respective capitals of their governorates. Kafr El Sheikh is about 2.5 hours' drive north of Cairo, roughly 140 km, and is located in the central northern sector of the delta. The northern border of the Kafr El Sheikh province is the Mediterranean Sea. Almost the same distance to the south of Cairo is Beni Suef. To the north of Beni Suef is Giza; to the west, the Fayoum; and to the south, Minya. Each of the villages selected in both Kafr El Sheikh and Beni Suef was an agricultural community typical of the area.

In Aswan the selected health units or centers and their code numbers shown in parenthesis were:

a) health unit Kazan Sharq (1): the village of Kakhor was sampled;
b) health unit Guzaria (2): the villages Gamma, Omrob and Harrob were sampled;
c) health center Abu Rish Bahri (3): the villages of Mal Katta and Mal Licta were sampled;
d) health unit Ga'afra (4): the villages of El Aratag, Shouna, Masagien, Falaleha, Omarab, Ali Abu Karime, El Sheikh Garat, Hedadoun, Hagar and Mahatta were all sampled;
e) health center Bimban (10) the villages of Kenisa, Abu Sharl, Omda, Mariab, Sheikh Mousa and Kabarra were all sampled.

In the Nubian resettlement area of Kom Ombo, the selected health units or centers and their code numbers were:

a) health center Ballana (5): the villages of Ballana 1,2, and 3 were sampled;
b) health unit Tushka (6): only the village Tushka was sampled;
c) health center El Malki (7): only the village of El Malki was sampled;
d) health unit Kurta (8): only the village Kurta 2 was sampled;
e) health center Kalabsha (9): the villages Kalabsha and Abu Khor were sampled.

The village of Kazan Sharq (1) is one of the most southern villages to be found in Egypt. This village is comprised of Nubians of the Kanoose tribe, and it should be pointed out that Kazan Sharq (1) and a few remaining villages just to the north, are also populated by Nubians who, because of

their location downstream from the AHD, did not have to be moved when Lake Nasser began to fill. Rather, this small population of Nubians are living in the same villages and the same homes that they were living in before the AHD was built, or, for that matter, from the last century and before.

The villages located at health units and centers 2,3, and 4 are communities typical of the area between Aswan and the Kom Omba plain and are located on the eastern bank of the Nile. These communities are characteristically found in high, dry, barren ground. Because the Nile valley is so narrow in this area, very little land is available for cultivation, and, therefore, what is available is far too valuable to build on. The cultivated areas are always found as a green strip between the village and the river, with the exception of Hagar in Ga'afra, which is located on a low barren hill next to the river. In this respect, these villages are unlike the ones in the Kom Ombo agricultural plain. From the northern point of the Kom Ombo plain, continuing north, the narrow valley gradually begins to widen as it passes through the next two governorates, Qena and Sohag. In these sites the villagers live at a greater distance from the irrigation canals and drains than villagers located in the delta or in Upper-Middle Egypt. Villages are found within the cropped area with increasing frequency as one travels north and east of Aswan into Qena and into Sohag. North of Sohag only a small fraction of the rural population resides in villages located outside the cultivated land, and these villages are often bounded on one side by their fields. The health center Bimban (10), was selected to represent villages typically built within the cultivated area. Six different villages all located in Bimban markaz (center) were sampled. The Bimban markaz, seen on the map in Figure 11, is located on the western bank of the Nile valley, almost directly west of Daraw. The villages are separated from the Nile and from the desert to the west by fields of sugar cane and wheat, and by palm groves, etc.

The selection of the Nubian resettlement villages was based on the previous study by Zawahry (1964). Each village that was surveyed in 1964 has now been surveyed again for this study. They are Ballana (Fadiga) (5), El Malki (Arab) (7), and Kurta (Kanoose) (8). In addition, two other villages were selected: Tushka (Fadiga) (6) and Kalabsha (Kanoose) (9), to increase the overall sample size.

DATA COLLECTION TEAMS

The primary data collection teams at each of the selected health units or centers were comprised of a physician, a laboratory technician, a sanitarian, one or two nurses and one or more aides. The team was led by the physician whose responsibility was to implement the collection of data and to ensure that all activities were completed according to the outlined procedures (see Appendix 4). The cooperation and employment of the various health teams was obtained through the Egyptian Minister of Health and through the respective regional offices of the Director General of Health. The director-general provided transportation to the sites and local security approvals, and saw to it that the materials necessary to continue were received at the study sites. In addition, a field supervisor, typically a vice-director-general, was assigned to follow the day-to-day progress in the

in the field and to work closely with the technical field supervisor (the writer). Aside from developing the plan of operation, acquiring materials, and training personnel, the role of the technical field supervisor was to coordinate the work at all levels at each of the twenty field sites.

The Egyptian Minister of Health assigned Dr. Baha Hashen, the director-general of all rural health services as a team representative from the ministry to the project. The EMH's services proved to be very helpful in establishing communications, transporting materials, collecting data, and obtaining cooperation of primary data collection teams.

The chief administrative team leader, Dr. M. Hussein, Dean of the High Institute of Public Health at the University of Alexandria, developed the administrative structure by which the various data teams and members were employed and paid, and closely followed the day-today developments in the field. In addition, Dr. Hussein obtained the necessary governorate approvals and security permits and provided the laboratory space and personnel for the analysis of the stool and urine specimens at the University of Alexandria.

REVIEW OF FACILITIES AND PREPARATION OF MATERIAL

The location for the examination of families was a rural health unit or a rural health center. Each health unit (for outpatients only) and each health center (small scale in-patient facilities available) selected was assessed for facilities needed for the survey. If facilities or equipment were lacking, they were obtained by the local field supervisor from the respective director-general's office. For the most part, these services were not needed as the health units and centers selected all had the required facilities and were in working order. These facilities included:

a) a light microscope, monocular model, with at least low power (16 mm focal length) and high power (4 mm focal length) objectives, and related equipment - slides, etc. Often these were manufactured in Czechoslovakia and were similar to Japanese Nikon models;

b) glass pipettes in sufficient quantity;

c) 250 cc glass conical flasks for urine sedimentation;

d) stool pans for the collection of stool specimens;

e) a hand centrifuge;

f) a balance for determination of weight and height.

The balances were made by Detecto Scales, Brooklyn, N.Y., U.S.A.; model Detecto-medic or similar. Microscopes, balances and hand centrifuges were placed in the health units and centers by UNICEF about 5 years previously in a program to update rural medical facilities in Egypt.

The additional materials needed by the health units or centers for the

recording of data and preparation of specimens were:

(1) printed data forms in Arabic;

(2) solution for preservation of stool and urine specimens;

(3) 10 cc plastic specimen vials or bottles;

(4) disposable applicator sticks for transferring stool specimens;

(5) permanent felt-tipped ink pens to label specimen bottles;

(6) a reference or methods guide for the correct procedure to be followed during the survey.

Printed Data Forms

The data forms for the clinical examination of the family, form code 01; and the data form for the examination of the house, form code 02; were first translated into Arabic at the High Institute of Public Health. The same procedure was used for the environmental forms coded 03 through 12. (All data forms and the methods guide are included in Appendix 2 and Appendix 3, respectively, of part 1.) The translated forms were reproduced by mimeograph. At the beginning of the field activities, all forms were reproduced at the High Institute of Public Health. Over 8,000 forms of 01 and 02 were necessary. Form 01 had three pages and 02 had four. Therefore, 56,000 sheets of paper were required just for these two forms. It soon became obvious that delays would develop if the forms continued to be mimeographed at the High Institute. Paper, stencils, and staplers were purchased and delivered to the local director-generals' offices, which took over the responsibility of providing printed forms.

Data Form Design--

The data forms for the examination of the family were based in part on the studies by Farooq and Nielsen (1966), Zawahry (1963), and Hussein (1972). At each health unit, a guide for the correct completion of the data form from the examination of the family was provided. This guide also included the correct method by which all procedures were to be carried out for the collection of field data. The guide served only as a reference and was not a substitute for instruction.

It should be pointed out, however, that special procedures were taken to determine age. The determination of age in a highly illiterate population is prone to error. Measures to minimize errors were adapted from Scott (1937). Scott (1937) found that it was more accurate to place a person in an age-group than to estimate the person's exact age. An age group sheet of 5-year age groups (starting from 0-1) was distributed with the methods guide and instruction for use was given to the physician. Birth dates were recorded only when government identification cards could be provided.

An attempt was also made to determine what medication, if any, the

individual had taken in the 360 day period prior to the day of examination. Only medications for parasitic diseases were recorded. Other medication received was recorded as "other." Details for the methods of obtaining the remaining data and data for the housing are described in the methods guide.

The design for the housing form, code number 02, was adapted from Mitwally and Sharqawi's (1970) article on measuring housing conditions in the rural areas of Egypt. For each data form a clear plastic overlay sheet with an English translation was made. These clear overlays provided an instant translation of the Arabic data form into English. As a guideline, the house to be examined by the sanitarian was defined as "the area lived in by the selected family."

PRESERVATION OF STOOL AND URINE SPECIMENS

It was clear from the beginning that there was considerable variation in ability to examine stool specimens for parasites and ova between laboratory technicians at the selected health units and centers. To compensate for the undesirable variability and to maximize the comparability from one study site to another, all stool specimens were preserved and sent to the laboratory at the High Institute. At the "central laboratory" the specimens were examined by a staff of trained personnel.

To implement this central approach for the examination of the specimens, a 10 ml translucent polyethylene bottle was provided for each individual at the selected sites. These bottles were purchased in Cairo and were 2 cm in diameter, 5 cm tall with a 1 cm opening in the top for which there was an inner cap and an outer screw cap, all polyethylene. On each bottle, the code number of the individual, comprised of the health unit number, the family code number, and the individual's number within the family, and his or her name was written with black, permanent, felt-tipped pens. Both pens and bottles performed well over the period of the survey. There was no occasion when the label came off, and the bottles, which were unbreakable, did not leak even though an occasional screw top had been deformed during the molding process.

The procedure for collecting the stool and urine for preservation is outlined in the methods guide. Two points should be added: 1) that the urine specimens were examined at the health units by the laboratory technicians. In addition, two drops of urine sediment were added to this stool specimen for preservation and examination later at the central laboratory. In this way a double check was provided on the examination of urine. The results of the on site examination were recorded on the data form for the examination of the family, form 01; 2) the transfer of the stool from the stool pan to the specimen bottle and the mixing of the stool with the preservative solution required something cheap and disposable. Broom straws, along with matchsticks and toothpicks, were all tested unsuccessfully. Very common in Egypt are small vegatable crates made by hand from palm fronds. The ribs of these crates were found to split nicely into straight wooden sticks which easily transferred and mixed the specimens. For preservation, the stool was mixed

with 9.0 to 9.5 cc of merthiolate-formalin solution adapted from the merthiolate-iodine-formalin concentration technique (MIFC) (Blagg, et al., 1955). Ova, cysts and trophozoites in fresh stool specimens collected in the MIF solution have been successfully preserved without deterioration of descriptive cytological features for a number of years. The exact period before deterioration begins is under study at the Naval American Medical Research Unit (NAMRU-3) in Cairo where the technique was first developed. Instead of adding iodine (Lugol's iodine) at the time of preparation when the specimen was mixed, as prescribed by this technique, the Lugol's iodine was added afterwards at the central laboratory just before the ether extraction phase. This alteration in technique, in addition to the fact that approximately 0.05 ml of urine sediment was being added, did not interfere with the desired staining intensity. By delaying the addition of Lugol's iodine at the health unit or center, the amount of materials that had to be delivered was reduced. This also assured that the Lugol's solution used was fresh, as it begins to deteriorate as a stain after one week. Thus, the urine was examined twice, once at the health unit or center and once at the central laboratory.

EXAMINATION OF STOOL AND URINE SPECIMENS

All specimens were collected from each of the study sites and transported to the parasitology laboratory at the High Institute of Public Health. At the laboratory, a team comprised of nine physicians examined the specimens. The team was supervised by three senior lecturers of parasitology at the High Institute.

All specimens received at the laboratory from a particular health unit or center were grouped together. There was no intended order within the group and a few specimens at a time were selected for examination from each group. This quasi-random method helped minimize the biasing effect of individual ability among the laboratory personnel.

The preparation of a specimen for examination was as follows:

1) the specimen was mixed and poured through a layer of wet gauze into a labelled centrifuge tube;

2) 0.6 ml of fresh Lugol's iodine was added to the specimen;

3) 4 ml of petroleum ether added in order to increase the specific gravity of the ova and cyst by extracting the lipid fraction. The tube was inverted and shaken vigorously;

4) the specimen was centrifuged for 5 minutes at 1500 rpm;

5) the top ether layer and fecal plug, and MIF layer were removed by suction, leaving the sediment and about 0.1 ml of MIF solution on top of the sediment;

6) the sediment was resuspended and a drop of this mixture placed on a microscope slide, and covered with a cover slip;

7) the slide was examined for characteristic ova, cysts, and trophozoites;

8) results were entered on a coded specimen examination form, an example of which is shown below.

Stool Examination Form (Code 15)

Specimen vial number:

Date:

Helminths:

Ascaris lumbricoides 1
Trichuris trichiura 2
Enterobius vermicularis 3
Ancylostoma duodenale 4
Strongyloides stercoralis 5
Taenia sp. 6
Trichostrongylus sp. 7
H. nana 8
H. heterophyes 9
F. hepatica 10
F. gigantica 11
S. haematobium 12
S. mansoni 13

Protozoans:

Giardia lamblia 14
E. histolytica 15
E. coli 16
E. hartmanni 17
Iodamoeba butschlii 18
Endolimax nana 19
Chilomastix mesnili 20
Trichomonas hominis 21
Dientamoeba fragilis 22

Examined by:

The coded specimen form includes a place for the code numbers, date, form code and code number of the examiner at the laboratory who examined the slide and places for indicating the presence of the various parasites screened. Only one slide for each specimen was examined.

An in-laboratory test was used to obtain data on individual examiner error. One specimen each day was examined by all members and the results scored independently. It was requested that the personnel examine the "test" slide in the same fashion as all other slides. The exam results were not

shown to the personnel, and it was emphasized that this was a procedure to estimate error rather than a proficiency examination. All laboratory personnel at the High Institute were closely followed and exhibited proficiency in the identification of the various parasites. The helminth ova are easy to identify as they are generally large and very characteristic in morphology. Proficiency was assured by comparing sample specimens with the NAMRU-3 laboratory.

SELECTION OF THE SAMPLE POPULATION

A systematic sample was taken at each study site. The unit of selection was the family. All members of each family in the sample were examined. From each study site about 200 families were selected systematically from a list drawn up from the village or villages to be sampled that included all the families of the village or villages and all the members of each family. By selecting 200 families per health unit or center, a sample total of approximately 700 to 900 persons was estimated. The target sample size for all study sites in both studies was between fourteen and eighteen thousand. The family list was the sampling frame. For purposes of selecting the sampling unit (the family), the family was defined as a man, his wife or wives, and all unmarried offspring. This definition was easy to use and fairly stable, i.e. the average number of persons per family did not vary greatly from site to site, though in Upper Egypt, the families were somewhat smaller. (Note that not all offspring of a selected married female may have been examined.) All selected family members were accounted for. If a member did not attend the examination, an explanation of why the member was not present was stated on the family examination form. No attempt was made to replace those who would not come, were absent at the time of the survey, or had died.

To make the selection of the families, an up-to-date list of family names and members, or sampling frame, was required. Generally, a frame was available but often out-of-date by four to five years. In order to avoid delaying the start of the survey, the following procedure was implemented. The total number of families in the old list was divided by 200. The number obtained, for example 3.4, was rounded off to the next higher number and added to one (two or three in other cases depending on an estimate of how many new families would be added). In this example, with a starting list of 680, every fifth family would be selected starting from a random number between 1 and 5. The frame would immediately begin to be updated, adding new families at the end of the list, and the examination of the selected families starting from the first selected and proceeding sequentially was also begun. The up-dating was always finished long before the examination of the first selection of families could be completed. The selection of every fifth family according to this example would result in an under-selection, i.e. less than 200 would be selected. In this case, about 136 families would be selected if 120 new families were added to the original list of 680. After the examination of 136 families, 64 families would have to be reselected from 664 remaining unselected families by selecting every tenth family. Re-selection being made without replacement, a total of 202 families would be selected and examined. This approach was used throughout the study, with

two or more samples (one or more reselections) from each site being taken in this fashion. Each selected family was circled and serially numbered in the list of family names and members.

The serial number for the family became the serial code number for that family. The members of the family were listed serially starting with the first person examined on the family examination data, form 01. This gave each individual that was examined in the survey a unique code number comprised of the number of the village, the family serial code number, and the individual code number within the family. The code number 01,001,01 identified the first person in the first family selected at the health unit 01, Kazan Sharq. The health unit or center code number and the family serial code number were used to identify the data froms 01 and the housing data forms 02. The data form 02 was completed for each house of each of the selected families. These forms were matched with the family 01 forms by coding the 02 forms with the health unit or center number, the house number, and family serial code number. The same sample size (200 families) was used throughout the survey, rather than selecting a given proportion of the population at each site. Therefore, the sampling fraction varied from site to site. This was done for administrative reasons, and because it was desired that the completion of the survey of the familes and the environment be roughly during the same period of time at all sites. The reason for this was that by carrying out the survey at the different sites over the same period of time, the possibility of seasonal variation of the parameters measured between the sites would be negated.

It was estimated that 200 families would yield a sample of about 800 individuals. This sample size was felt sufficient to give the estimates of the various parameters sampled with adequate precision at each site. The systematic selection of families was used as opposed to a purely random method for two reasons: 1) the systematic selection more often than not gives greater precision. With a systematic selection, no isolated groups, individuals, or houses are left unrepresented in the sample, as might inadvertently happen with a random selection; 2) the selection of the families for examination could proceed immediately without waiting for an up-dated family list. A random sample would be impossible to select before the list was completed because the added group would not have a known possibility of being selected in the first round.

EXAMINATION OF THE ENVIRONMENT AND THE POPULATION

Before the survey could begin, each health unit or center had to receive the necessary materials and the personnel had to review the methods for the correct filling in of the data forms and the correct method for preparing the stool and urine specimens. The up-dating of the family list was always the first activity, followed by the selection of the families. In order to obtain the cooperation of the village members, a meeting was held with the village council, the local physician and the field supervisor, to explain the purpose of the survey and solicit the aid of the council to overcome any difficulties. On occasion, the director-general of the governorate attended these meetings. Only after the personnel at the health unit or center showed proficiency with the different aspects of the data acquisition, was the

examination begun.

Generally, a routine was established where the sanitarian would go to the selected family's house, complete the housing form and instruct the family to go to the health unit or center the following day. The instructions included telling the family members that the information obtained would be held in strictest confidence and that specimens of stool and urine would be requested at the health unit or center. At the health unit or center, the selected family members would be given a numbered steel pan and a numbered tin cup and requested to provide a specimen of each at some point during the examination.

By obtaining the specimens from the selected family members at the health unit or center, proper identification of the specimens could be guaranteed. This is a unique feature to this survey. Scott (1937), Farooq and Nielsen (1966), and Zawahry (1963) all obtained their specimens by providing specimen containers to the heads of the household of each of the families selected.

There were exceptions, most notably at Kurta (8) in the resettled Nubian area. The water supply in the laboratory at Kurta (9) was the most inadequate of all the selected sites. The piped water supply was limited to a few hours a day and frequently failed for periods longer than 48 hours. Water rarely came to the health unit's laboratory. At Kurta (8), protected water was used first for drinking and cooking before it went for other purposes.

Because of this lack of water at the health unit, selected family members refused to give stool specimens. Under the circumstances, the methods of Scott (1937), Farooq (1966), and Zawahry (1964) were employed. Thus the correct specimen was obtained. Also, a large metal reservoir was given to the health unit laboratory so that water could be stored and available to clean equipment.

Trips to the field to initiate the survey activities were made in early April, 1976. By May, 1976 all units and centers had begun the collection of data. After the survey had begun, each field site was repeatedly visited. During these visits, additional materials were supplied, completed data forms and prepared specimens were picked up, and, if required, a reselection was made. This evaluation included the following:

1) a check to see if the names on the completed 01 and 02 forms corresponded to the names in the family list;

2) a check to see if the correct code numbers were being used;

3) a check to see if the code number on the specimen bottles corresponded to the code number on the family form 01;

4) a check to see that the housing forms 02 were being correctly completed. This was done by selecting several completed forms and going to the respective homes and seeing if the completed

forms agreed with the actual conditions;

5) a check to see if all the families in the village were included in the family list. This was done by going to the village and randomly selecting a house to see if the occupants were listed in the book. On no occasion was a family located that had not been included. It should be pointed out that 1) the sanitarians are well-trained in this respect; and 2) they were often residents of the village who knew the villagers well, and were actually related to many of them;

6) to review any problems or obstacles being met and to resolve them;

7) to review the general progress, and to determine if the health unit or center was on schedule. Since only part of the working day could be allotted to the examination of the family members or the environment at the health unit or center, it was requested that approximately 20 persons per day, or five to six families, be screened at a time. The examination of the families and their environment at each site, which was to be completed in about three months, was actually 95% complete after five months;

8) to review the method of examination of the selected family members. This was done by observing the completion of the family form 01, with the physician at the health unit or center during a visit when examinations were being carried out. First, a family that had been examined just prior to arrival was recalled and re-examined, while checking the completed form for discrepancies. Secondly, the completion of the family form was followed through on a family who had not been examined. This was especially helpful in detecting errors in obtaining and preparaing specimens. Idiosyncratic procedures were noted during this time. Those which did not in themselves affect the collection of data were usually allowed to continue, as changing procedure would risk causing errors;

9) confirmation of the methods used at the health unit or center for completion of the environmental data forms were reviewed in the same fashion as was employed for checking the housing forms;

10) on occasion, persons or families would come to the health unit or center requesting to be included in the examination. If the person was elderly and a relative of a selected family or a village leader who had not been selected, forms were completed and specimens taken. No code numbers apart from the health unit number were given to these individuals. Data from these forms were not included;

11) an inventory of all the materials;

12) one of the most important checks was to see if the specimens of stool and urine were correctly examined, prepared and labelled. From the very first it was stressed that the right stool and the right urine be placed in the right bottle in the corrent manner. (The correct procedure was outlined for the laboratory technicians

in Arabic.) This procedure was reviewed frequently at the health units and centers at the time when specimens were being provided by the selected individuals.

DATA MANAGEMENT AND ANALYSIS

For this study, 3,859 house data forms were executed for the examination of the dwelling units. An almost equal number were completed for the examination of the family. About 400 data forms were completed for the various environmental aspects of the village sites. Exactly 15,665 stool specimens were received. Ultimately, over 40,000 cards were keypunched.

When raw data in these quantities are obtained, major efforts have to be made to keep the data from being misplaced, lost, or damaged before it can be processed. This was aggravated by the distances involved between the 20 different study sites, as well as by the lack of good communication systems. Invariably, staff at the health units faced problems after actually starting the survey that were not anticipated during the training phase. Most often the problem was solved by a change in coding procedure which did not affect the final accuracy. For example, on the housing form (02), in an unanticipated situation, the correct answer required the selection of more than one number, although only a single answer had been anticipated, and only one box had been provided on the data form. The examiners simply wrote in two numbers, or whatever the combination may have been, in the given box. This alteration was easily handled when the coding sheet was designed. The process was not always as uncomplicated as this and new combinations necessitated redesigning the code sheets.

To minimize problems of data management, a complete inventory of the number and amount of materials delivered and received from each study site was kept. Before data forms were accepted, they had to be checked for completeness, consistency and accuracy.

All completed forms were packaged and delivered to the Cairo University Statistics Center. Code sheets were designed, tested, and redesigned. The final coding sheet for a particular form was reproduced at the center by offset printing.

Before transferring the data onto code forms, a code book or code key was developed for each type of data form. The questions on the family examination form 01 concerning diagnosis and medication received were the only examples of truly open questions, and required continued updating of the code book. The greater part of the coding was simply copying a selected number onto the code sheet.

Coded data were verified on a sample of forms from each site before punching. Punching formats were designed from the code sheets, i.e. data were punched directly from the code sheet. At the computer center printed listings of each site were made and checked against a sample of original data forms. For listing the data on magnetic tape, the punched cards were sorted by site, family and individual, and a file on magnetic tape was created for each category of data form.

A series of Fortran IV programs were written at the Cairo University Statistics Center for use on a Data General 'Nova' computer. These programs were for:

1) preparing listings of various sub-sets of data;

2) basic tabulations of important variables in the data set. A number of tabulations were used to follow the work in the central laboratory, and were designed specifically to detect errors and inconsistencies made by the laboratory workers;

3) sequencing, matching, and renumbering of specimen data;

4) validating and examining the consistency of coded data;

5) eliminating duplicates in the specimen data; and

6) writing the data set onto magnetic tape files.

The complete data set stored on magnetic tape was transferred to the University of Michigan's computing center for continued analysis. At the University of Michigan, the Michigan Terminal System (MTS) and the Michigan Interactive Data Analysis System (MIDAS) were used to:

1) re-edit various sub-sets of data based on the results of verification programs run in Egypt;

2) match and merge the data from the family examination with the data from the specimen forms and housing forms for the creation of a master data file; and

3) to complete, following step number two, the descriptive analysis and the assessment of relationships between variables in the data were completed.

Adjustment Scheme

Since the sampling fraction and the age structure of the sample varied from study site to study site, an estimate of prevalence made by simply adding together all those infected and dividing by the total number sampled in a given area, for example in Kafr El Sheikh, would be incorrectly weighted. To adjust for this, a procedure was formulated using a series of MIDAS commands. An estimated number infected was calculated for each age-sex group for each site in a given area of study. The age-sex specific prevalence at each site was used to make these estimates. The estimated numbers infected in each age group for each site were added together and divided by the sum total of the population of all villages studied in the area. This result was the adjusted age-specific prevalence. The sum of all these estimated to be infected, divided by the total population from all sites, equalled the overall adjusted prevalence for a given area. Sex-specific adjusted prevalences were calculated using the same procedure, but selecting only male or female cases.

CHAPTER V

RESULTS AND DISCUSSION

PARASITIC INFECTIONS

The general overall crude prevalence in the samples of the four major rural study areas; the north central delta, Upper-Middle Egypt, Upper Egypt, and New Nubia has been determined. Table 9 is a master table showing the percent positive by each village site for all parasites screened for in the examination of the stool. This table also includes data obtained on the presence and type or absence of a latrine and whether or not it was used, and data on the number of persons per house. A separate table, Table 10 , was prepared to show the distribution of water supply in the different study areas or regions. The number of persons per standpipe (a public spigot) by village, however, is given in Table 9.

It should be noted that the different categories in Table 10 are not mutually exclusive. Each cell in the table could reach 100%. The percentages shown simply indicate a preference of water source. For example; in the first column, 90% of the population in Kafr El Sheikh stated that their drinking water was obtained from public standpipes; 19.4% cited the canal as a source or at least 9.4% obtained drinking water from both sources. (When significant tests were used to determine if the source of water was related to the prevalence of a specific parasite, this "overlap" was corrected for by selecting a program which created exclusive categories and eliminated cases which had claimed more than one source.)

The results of Table 10 clearly demonstrate the demand for protected water sources. The corresponding figures in Table 9 show the number of persons per standpipe and reveal the intense use placed on these sources. The lowest number of persons per standpipe was 85; some villages had no piped sources at all, and the overall means of 407 persons per standpipe in the downstream study sites is somewhat higher than that suggested by Furina (1975). Obviously such an intense competition for protected water supplies limit its usefulness and potential benefit. Although the data in Table 11 do not strongly suggest a relationship between the prevalence of the helminthic and protozoan parasites, except for the schistosomes, every attempt should be made to improve and expand this service.

The infection of the sample with helminthic parasites was found to be remarkably low, as can be seen in Table 9. The prevalence of hookworm, H. nana (dwarf tapeworm), Taenia (beef or pork tapeworm), and Enterobius (pinworm) were low in all study areas including the Nubians. Ascaris was only moderately elevated in the Nile Delta study sites (8.4%) but not elsewhere. The Entamoeba infections were by far the most prevalent and were found consist-

ently high in all study sites.

It became apparent very early in the examination of the stool specimens that the helminthic infections, Ascaris and Ancylostoma were being detected at a frequency much lower than expected. A quick glance at Table 2 shows that both infections were much higher in the past. The expectation that higher frequencies should be observed resulted in a close evaluation of the MIFC technique and its employment. The MIFC protocol was reviewed as well as the cytological features of the respective ova. Both aspects were found to be correctly used, as neither method truly qualifies as a technically difficult procedure. Furthermore, the genus Entamoeba was readily and frequently identified in the specimens as well as the helminth S. mansoni. Specimens obtained elsewhere and known to be positive for either Ascaris or Ancylostoma were correctly identified without fail using the MIFC procedure. The conclusion is that these two helminthic infections, Ascaris and Ancylostoma, have decreased in our sample sites over the period of a decade. (The time span between this study and the most recent historical data is 10 years.)

As was pointed out, direct comparisons between prevalence studies in Egypt are limited. However, the differences seen between this study and past studies in regard to these two helminthic infections is dramatic and too great to be explained on methodological differences alone. The past evidence clearly points to a much higher prevalence. Assuming that the sample sites studied here were not freakishly typical, and the prevalence for these two parasites have indeed fallen, then the most probable explanation for decreases in the infections is the wholesale distribution of pharmaceuticals such as piperazine. All rural health centers and units stock this drug and prescribe it frequently at little or no cost to the patient. Furthermore, this drug was frequently sited on the data forms as having been prescribed within the previous year of the study.

The exposed foot is the classic portal of entry by the infective larvae of Ancylostoma. For a number of years now, cheap plastic footwear has been available to the population in general and especially to the lower social-economic classes. The use of this footwear breaks the hookworm transmission cycle. The readily observable use of plastic footwear, of any kind, throughout rural Egypt has no doubt contributed to a decline in the prevalence of this infection.

There were significant differences between study sites in a given area. Notable is the hookworm distribution in Aswan where the non-desert villages of Bimban (10) had more hookworm (1.2%) than any of the other "desert type" villages. Also interesting is the decrease in Ascaris infection outside the delta. Although the prevalences are much lower, the distribution still parallels that found previously by Scott (1937a), i.e. decreasing from north to south. No significant differences were seen between sexes or age for Ascaris infections. Prevalence in the very young ages were as high as the older ages. Unique age or sex distributions were not noted for any of the parasites investigated. (The tables depicting age-sex prevalence relationships and other descriptive aspects are included in an appendix for tables.) This rather unusual arrangement for tables was prepared because of the very large number of tables prepared for this report, greater than one hundred. The

vast majority of these tables are basically descriptive and include tables with information on the environmental parameters that were also measured. Specific information sought for from these tables should be made by subject as each table's heading is indexed on the front pages of the table appendix.

The presence of a latrine was significantly associated with a reduced prevalence in Ascaris infection, Kafr El Sheikh and Beni Suef, but not in Aswan. Table 12 shows these results in addition to five other selected parasites. Generally, the results were not encouraging. Only in one other case was the presence of a latrine favorable, i.e. for E. coli infections in Beni Suef.

The high prevalence of the Entamoeba species indicates that personal hygiene for the populations sampled is still inadequate. The quality of water supply did not relate well to the prevalence of these organisms either. (See table appendix on parasitic infections and water supplies.) This may be a reflection of limited water supply and use.

TABLE 12

Relationship Between Latrine and Infection With Selected Parasites in the Three "Downstream" Study Areas

PARASITE	PERCENT POSITIVE					
	Kafr El Sheikh Latrine		Beni Suef Latrine		Aswan Latrine	
	Yes	No	Yes	No	Yes	No
A. lumbricoides	8.0	12.0	0.7	3.2	3.9	2.1
Ancylostoma	1.4	1.1	4.0	2.6	0.3	0.3
H. nana	2.4	1.1	1.0	1.2	5.7	4.7
G. lamblia	6.5	5.1	3.5	3.4	10.9	6.4
Entamoeba coli	40.5	33.0	39.4	49.4	37.2	31.4
E. histolytica	4.5	3.7	6.0	5.4	7.2	5.2

Table 13 shows the percentage of persons infected with any single parasite and any two or more parasites. The sampled population from Beni Suef had consistently higher numbers of positives than the other two downstream locations sampled.

Table 14 is a summary of the percent positive in all four study areas. The table was constructed to give the reader a quick overview of the findings for eight of the more prominent parasitic infections screened for in this study.

TABLE 13

Multiparasitic Infections in the Study Areas

NUMBER OF INFECTIONS	PERCENT POSITIVE/CASES		
	Kafr El Sheikh	Beni Suef	Aswan
Any one parasite	42.7/1557	53.2/1518	42.7/1227
Any two parasites	20.1/ 731	44.5/1271	15.6/ 449
Any three parasites	5.2/ 188	14.5/ 414	3.7/ 107
Any four parasites	0.9/ 31	3.2/ 91	1.0/ 28
Any five parasites	0.1/ 5	0.4/ 11	0.1/ 4

TABLE 14

Percent Positive of Selected Parasites By Study Area

PARASITE	AREA			
	Kafr El Sheikh	Beni Suef	Aswan	Nubia
Ascaris lumbricoides	8.4	2.1	3.1	2.3
Enterobius vermicularis	1.3	2.1	1.0	1.4
Ancylostoma duodenale	1.5	3.3	0.4	0.3
Taenia sp.	0.1	1 case	2 cases	0.0
Hymenolepis nana	2.3	1.0	5.2	5.5
Giardia lamblia	6.2	3.5	9.0	9.7
Entamoeba histolytica	4.5	5.8	5.5	7.5
Entamoeba coli	39.2	44.8	34.8	48.6

The results of the Nubian study were based on methodologies and sampling sites used by Zawahry in 1964 (as described in the methods section) just prior to their relocation in Kom Ombo. This design was selected in order to strengthen the validity of comparisons between the results of these two studies.

Table 15 shows the prevalence for the same eight parasites mentioned above and the respective prevalence levels before and after relocation. No

cases of hookworm infection were seen in Old Nubia (Table 2). Seven cases were detected by this study; perhaps as results of the increase in sample size over the one in 1964 by a factor of four.

TABLE 15

A Comparison of Parasite Prevalence (%)
Before and After Resettlement in Nubia

PARASITE	1964*	1978
Ascaris lumbricoides	6.6	2.3
Hymenolepis nana	7.7	5.5
Enterobius vermicularis	0.1	1.4
Taenia sp.	0.1	0.0
Entamoeba histolytica	3.2	7.5
Entamoeba coli	34.3	48.6
Giardia lamblia	2.7	9.7

*After Zawahry, 1964.

Overall, there was very little meaningful change in the prevalence of these parasitic infections. Except for Entamoeba, the prevalence levels were favorably low before and after resettlement. It was expected that the increased crowding necessitated by the resettlement plan would result in an increase in a number of communicable infections including the parasite diseases mentioned here. The slight increases seen in the protozoan infections may be a result of this change in living conditions. This increase can only be considered alarming if it indicates a continued upward trend. Follow-up surveillance is needed however, before this can be determined.

ENVIRONMENTAL FACTORS

Critical environmental measures such as water supply and water disposal were analyzed in the previous section under Parasitic Infections in a brief attempt to establish a relationship or association between these two variables. There are other interesting descriptive features concerning the water, wastewater and other environmental variables that were measured and should be elaborated on. (The details of the environmental data can be found in the appendix for tables; subheading Environmental Measures.)

The outstanding features, however, are the fact that protected water supplies are present in almost every Egyptian village, and more rural houses

in the sample had a latrine than did not. Two of the three village standpipes relied heavily on ground water raised by handpumps. Only the villages of Kazan Sharq (1) did not have some type of protected source and were forced to carry from the river bank. Even here, public standpipes were being installed as the field activities for this study were closing in the fall of 1976.

THE NUBIANS

In terms of water, wastewater and housing, the Nubians benefited by their relocation to Kom Ombo enormously. All the new houses have electricity or have readily available points for connections into the village supply. Many homes, especially in Kurta (8), sprout television antennae. (Most villages of rural Egypt now have at least one television set, usually located at a village tea house. Small cheap battery-driven radios are also common and provide the creative environmental health worker with an important mechanism for the development of environmental health education and awareness.) All Nubian homes have latrines and the only source of water for the new Nubian homes is from public standpipes. Furthermore, the Nubains now have access to the medical care system through the rural health centers and units found throughout the resettlement area. Schools, social centers and club buildings have also been provided. The mere fact that the Nubians are no longer a remote population, difficult to travel to, and remote from the mainstream of Egypt's overall development, is an environmental improvement in itself. It is unfortunate that many Nubians have voiced a desire to return to old Nubia by establishing new settlements along the shores of Lake Nasser. To do so would: (1) dangerously expose them to schistosomiasis transmission via the Lake Nasser fishermen who have been found to have a high prevalence of this infection in their own groups (Dazo and Biles, 1971); and (2) to provide a mechanism of malaria transmission from the Sudan into the downstream populations of rural Egypt (not to mention the devastating effect malaria would no doubt have on their own populations).

THE DOWNSTREAM STUDY SITES

Upper-Middle Egypt (Beni Suef) had more persons per standpipe and fewer homes with latrines than did the other two downstream study areas, 928 and 64.6% respectively. It is interesting that the multiparasitic infections (Table 13) are higher in this area also.

The typical village house in the three downstream study sites was made of mud brick with a packed earth floor. Stone, red brick, or mud and red brick were also common. Few houses examined stood alone. Many were bound on three sides (65.2% in El Hamra (17), Kafr El Sheikh) and reflect the close housing patterning necessitated by a limited amount of agricultural land, characteristic of Egyptian villages, towns and cities. Actually, crowding (persons per room) is less severe in the rural areas than in the urban ones. (Obtained from the results of comparing figures from this study with data collected by the 1960 census; Capmas.) Although conditions have changed since 1960, the direction has been entirely toward the urban centers. Severe crowding conditions in the home could not be described for Aswan and Nubia even if the rooms of these homes were small. The stable (used for chickens,

rabbits, ducks, goats, etc.), when located within the confines of the house (typically adjoining the courtyard), is a serious environmental hazard. Most homes in Kafr El Sheikh or Aswan had them inside. The Nubian homes were designed with inside stables.

The stable floors are intense fly-breeding areas and are used in some homes as a handy and secluded location for defecating (Headlee, 1933). It is obvious that the transmission of a number of communicable diseases, including several infections not measured by this study, could be enhanced by the presence of the stable. The stable is an important site for improvement and must be included in environmental health programs. Currently, they are not.

Related to the stable and domestic animals is cooking with dried dung cakes. A detailed assessment was made on what different types of fuels were used for cooking. Dung alone was used most frequently in Beni Suef, and dung in combination with some other fuel (kerosene or charcoal) was by far the most commonly sited source of cooking fuel. Fewer studied homes in Aswan cooked with dung than in the other downstream sites. It appeared that if other cooking fuel, besides dung, could be obtained it was preferred. Every attempt should be made to help the villager exercise this preference.

Animal waste may frequently be dumped in the street, in the yard or stable (where it originated), or sometimes in the canals. The street, where all village household wastewater is disposed, also is the most common site for dumping animal waste material. In the dry, hot south of Upper Egypt, desication remedies a sizable proportion of this problem. In the delta, especially during the wetter months, the unpaved village streets may become almost septic and impassable.

An encouragable number of homes were painted (inside, outside, or both) and many had electricity. The villages of Aswan, of course, benefitted most from the nearby location of the High Dam, but the results indicate that rural electrification programs are extensive and most likely growing. There was at least one or more television sets in every village.

The pit latrine was the type of latrine most frequently seen and by far the major of these latrines were sited as inside the house. Only in Bimban (10) were latrines most often located in the stable. Some had latrines and did not use them, especially in Mahalet Moussa (19), Kafr El Sheikh (17.0%).

The shortage of water for the home is interesting. Throughout the country-side, and seen also in urban locations where people congregated, are zirs or large earthenware water containers. These containers hold about 20 liters, have tapering pointed bottoms, and are slightly porous. Because of the pointed ends, various types of support structure are necessary, for the vessel will not otherwise stand. Furthermore, the vessel is supported so that the pointed tip does not touch the ground. The zir when full, "sweats", that is, small amounts of water seep through the pores and blankets the vessel in a wet film of water that collects at the pointed tip and is used for drinking. The "sweating" also provides a measure of coolness to the container due to rapid evaporation in the hot and dry climate of Egypt.

Water for drinking is also obtained directly from within by, more often than not, a tin can. Some zirs have lids.

Over 95% of the homes studied had zirs and used them to store water collected either from standpipes, handpumps, canals or other sources. Even homes with piped in water supplies (for example, a single tap in the courtyard) would use the zir to store the family's water supply. One might wonder why water would be stored in an earthenware zir when a piped source is available. The reasons are (1) because the water supply via the pipe is erratic; (2) the water from the zir is cooler; and (3) in the opinion of the rural Egyptian who has been drinking from the zir all of his or her life--water tastes best from a zir. All water that comes into the house, where it was used for drinking, cooking, washing, laundry, etc., passes through the zir storage container. From personal observation, it seemed that bigger houses and families had more zirs. The investigators were often told that the dried pit of the apricot would be ground into powder and added to the turbid water of the zir, apparently as a coagulant. These points are made because any health improvement program must consider the hygienic characteristics of the zir, and the role it plays in the rural Egyptian household.

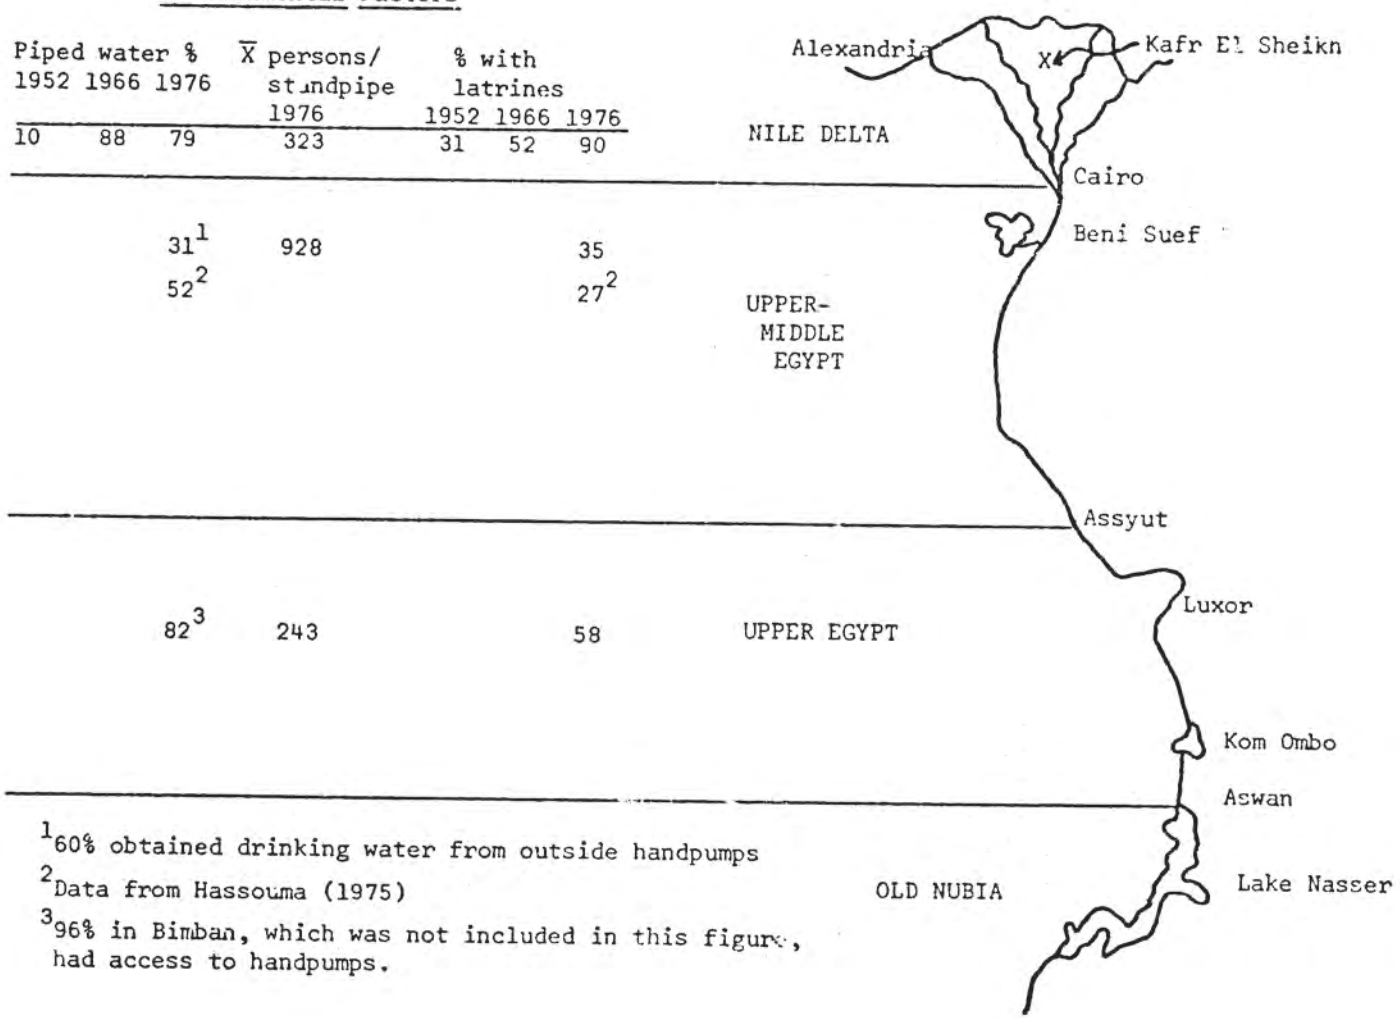
APPENDIX I.1 COMPOSITE TABLE FOR ENVIRONMENTAL FACTORS

Environmental Factors							
Piped water %			$\bar{X}$ persons/ standpipe	% with latrines			
1952	1966	1976	1976	1952	1966	1976	
10	88	79	323	31	52	90	NILE DELTA
		31[1]	928			35	
		52[2]				27[2]	UPPER-MIDDLE EGYPT
		82[3]	243			58	UPPER EGYPT
							OLD NUBIA

[1] 60% obtained drinking water from outside handpumps

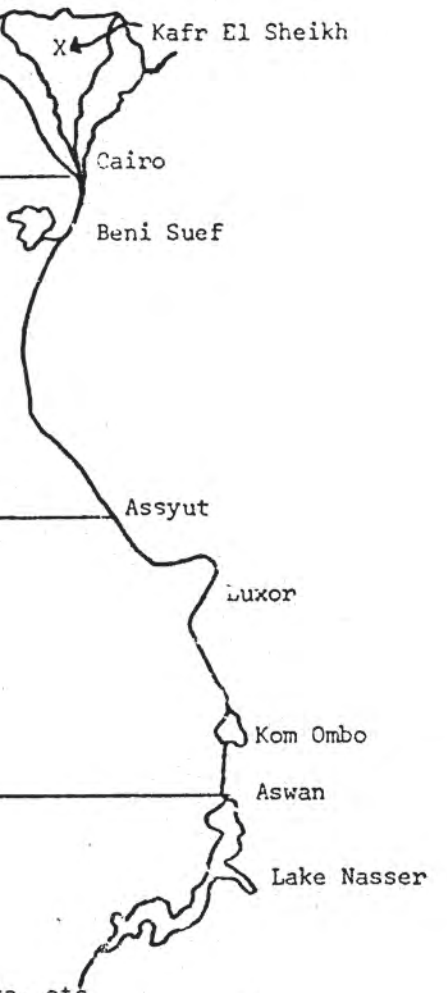
[2] Data from Hassouma (1975)

[3] 96% in Bimban, which was not included in this figure, had access to handpumps.



APPENDIX I.2 COMPOSITE TABLE FOR IRRIGATION AND POPULATION

Irrigation			Population	
1935	1955	1976	1976	
6+	6+	6+[1]	11,635,949 59.4%	NILE DELTA
+	+	+		
+	+	+	4,772,647 24.4%	UPPER- MIDDLE EGYPT
+	+	+		
-	+	+		
-	+	+		
-	-	+	3,224,260 16.2%	UPPER EGYPT
-	+	+		
-	-[2]			
-	+			OLD NUBIA
-	+			



[1]Each plus represents the presences of perrennial irrigation schemes in a governorate. There are 6 governorates in the Nile Delta, etc.

[2]This is from 1964 data

APPENDIX II.1

Total	22	223	123	210	190	199	199	200	200	200

APPENDIX IV.2 TABLE XXIII

Number of Houses by Presence of Latrine, Raw Counts, for Aswan and New Nubia

	Study site code									
	Aswan					New Nubia				
Latrine	1	2	3	4	10	5	6	7	8	9
Present	5	201	15	48	96	186	192	196	195	199
Not Present	2	7	89	73	94	4	4	3	1	0
No information	15	15	19	89	0	9	3	1	4	1
Total	22	223	123	210	190	199	199	200	200	200

TABLE XXIV

Number of Houses by Latrine Use, Raw Counts, for Aswan and New Nubia

	Study site code									
	Aswan					New Nubia				
Latrine Use	1	2	3	4	10	5	6	7	8	9
Yes	2	200	15	49	95	187	191	196	187	199
No	1	5	106	68	95	3	5	2	9	0
No information	19	18	2	93	0	9	3	2	4	1
Total	22	223	123	210	190	199	199	200	200	200

APPENDIX IV.2 TABLE XXV

Number of Houses by Presence of a Cover for the Latrine, Raw Counts, for Aswan and New Nubia

	Study site code									
	Aswan					New Nubia				
Latrine Cover	1	2	3	4	10	5	6	7	8	9
Present	0	196	15	43	95	115	192	194	24	199
Not Present	1	7	106	69	95	76	4	4	168	0
No information	21	20	2	98	0	8	3	2	8	1
Total	22	223	123	210	190	199	199	200	200	200

TABLE XXVI

Number of Houses by Type of Latrine, Raw Counts, for Aswan and New Nubia

Type of Latrine	Study site code: Aswan 1	2	3	4	10	New Nubia 5	6	7	8	9
Bore hole	0	11	0	4	1	4	0	1	3	2
Pit	1	168	7	46	0	7	5	1	174	197
Pit with Masonry Lining	0	21	9	1	94	176	187	191	1	0
No information	21	23	107	159	95	12	7	7	22	1
Total	22	223	123	210	190	199	199	200	200	200

TABLE XXVII

Number of Houses by Location of Latrine, Raw Counts, for Aswan and New Nubia

Latrine Location	Study site code: Aswan 1	2	3	4	10	New Nubia 5	6	7	8	9
Inside	3	177	7	19	17	191	190	191	196	198
Outside	0	23	2	22	1	0	1	3	4	0
Stable	0	1	0	0	65	0	1	0	0	0
No information	19	22	114	169	107	8	7	6	0	2
Total	22	223	123	210	190	199	199	200	200	200
